

Topics

- 1) What does Object do for us?
 - a) toString()
 - b) equals()
 - c) hashCode()
 - d) clone()

Gee, that's it? That should be simple, eh?!

toString()

toString()

- Automatically called when:
 - you concatenate an object with a string.
 - you print an object with print() or println().
- Default implementation
 - Object.toString() prints class name and hash code.
 ToStringExample@6876fb1b
- Reasonable toString() Structure

```
@Override
public String toString() {
  return getClass().getName()
    + "["
    + ... fields=values....
    + "]";
}
```

```
getClass() gets the..
class descriptor
```

getClass().getName() returns the package name and full class name.

toString() Guidelines

- toString() should:
 - return "a concise but informative representation that is easy for a person to read" [Javadocs for Object]
 - include all important fields in a human readable format
- Value Classes
 - For a "value" class (like PhoneNumber, Department) return.. an obvious canonical form for UI output "(604) 123-4567", "CMPT"
 - Not for formatting complex objects for the UI:
 "Minion 'Horrible Harry' has 5 evil deeds"
 - complex formatting should be done by the UI
- toString() not to replace getter functions;
 never get access to internals by parsing output of toString()

24-04-02 5

toString() w/ Inheritance

```
class Employee {
     private String name;
     private int salary;
     @Override
                                                      getClass().getName()
     public String toString() {
                                                       gives the class of...
          return getClass().getName()
                                                       the object, not the class
                    + "[name="+name
                    + ",salary="+salary
class Manager extends Employee {
                                                        public static void main(String[] args) {
     private int bonus;
                             super.toString() -> getClass().getName()
                                                            Employee bob = new Employee(...);
                             which returns the class of object Manager,
     @Override
                             not the super class Employee
                                                            System.out.println(bob);
     public String toString() {
          return super.toString()
                                                            Manager sarah = new Manager(...);
                    + "[bonus="+bonus
                                                            System.out.println(sarah);
                                             Employee[name=Bob,salary=50000]
                                             Manager[name=Sarah,salary=100][bonus=200000]
24-04-02
```

equals()

equals()

• equals() checks if.. two objects have "logical equality"

```
• Common error:

Car a, b;

if (a == b) {

do a and b point to the same address?

}
```

Should use:if (a.equals(b)) {...do something}

```
But Object Provides:
public boolean equals(Object obj) {
...return this == obj:
```

```
Override equals() only when necessary
```

Equality

- Each class defines equals() as needed
 - Used by many classes to check equality.
 Ex: set checking for unique items.
 - Value classes (storing data) often need equals()
- Example: Strings
 - Two Strings equal if contents identical (characters AND lengths are the same)
- Example: ICBC Database
 - Two Cars are equal if. same VIN (vehicle id number) even if different colours (likely one repainted)

Casting Safety

equals() is defined on the class object, so we can compare anything with anything else, so we need to handle type conversion

To use o, must cast to Car.

However, this can throw an exception.

class Car {
 @Override

note that here the parameter is not Car type yet -> need to cast it, but if cast then throw exception ==> so we'll use instanceof instead to check

public boolean equals(Object o) {

Check o is..

same or derived class as this

(Must work for derived objects)

instanceof returns false if o is null

if (!<mark>(o instanceof Car</mark>) return false;

Car that = (Car) o;

generally care about with inheritance, if our code depends on "instanceof" of a base class, then we might be wrong => LSP violation if: to have client code care about the concrete type of the object

24-04-02

--> if we use instanceof because we want to check one weirdo

--> then we probably did it wrong cuz it violated LSP

3 types when we should use instanceof:

- + check like example above
- + ison
- + records?
- + switch

Complete equals()

```
class Car {
  private String make;
  private Date year;
  private int seating;
  private double weight;
  @Override
  public boolean equals(Object o) {
    if (0 == this) return true; could get rid of this line
    if (!(o instanceof Car)) return false;
    Car that = (Car) o; bcuz this is String and Date type
    return Objects.equals(make, that.make) read note below
         && Objects.equals(year, that.year)
         && seating == that.seating
         && Double.compare(weight, that.weight) == 0;
          comparing double is tricky as well -> used pre-defined method of wrapper class Double
          Double.compare is smarter than Double.equals
```

- Check if same object (efficiency)
- Check other object is correct class.
- Cast and check fields

Checking fields for equal

- null safe call to an object's equals()
 - Objects.equals(field, that.field)
 - Correctly handles nulls and does not throw exception
 - Calls the field.equals() method.
- floating point
 - Double.compare(field, that.field) == 0
 - Correctly handles -0.0 vs +0.0, NaN, etc.
- int/short/long/bool/...field == that.field
- Skip fields which are not part of the object's logical state (cached values, etc).

```
class Car {
  private String make;
  private Date year;
  private int seating;
  private double wgt;

@Override
  public boolean equals(Object o) {
    ...
  return Objects.equals(make, that.make)
    && Objects.equals(year, that.year)
    && seating == that.seating
    && Double.compare(wgt, that.wgt) == 0;
}
```

equals() contract

- For non-null x and y, equals() must be:
 - reflexivex.equals(x) must be true
 - .. symmetricx.equals(y) iff y.equals(x)"x and y must agree if they are equal"
 - transitivex.equals(y) && y.equals(z) means x.equals(z)
 - consistent
 value of x.equals(y) unchanged for multiple invocations
 - .. not-equal null
 x.equals(null) == false

Spot the Errors!

```
public class Truck {
    private String make;
    private Date year;
    private double weight;
                                        para should accept Object, and cast it to Truck
    public boolean equals(Truck o) { must accept Object; should @Override
        if (this == null) return false;
this can never be null; o may be null, but checked by instanceof
        if (! (o instanceof Truck)) return false;
         here: must cast o to Truck: Truck that = (Truck) o;
        return make.endswith(o.make)
                                             not symmetric - ex: "hello".endswith("lo")
                 && weight == o.weight
                                             and ("lo").endswith("hello")
                 \&\& year == o.year;
                                             For floating point, use Double.compare(...)
          use Objects.equals(x, that.x) on objects, x.equals(that.x) OK if non null
```

instanceof aside

- Use instanceof instead of .getClass()
- Checking identical class violates LSP: getClass() == o.getClass() only true for identical class
 - Cannot have a derived class... equal to a base-class object
 - Used with proxy classes, etc.
- With inheritance, instanceof can hit symmetry issues
 - car.equals(sportsCar) sportsCar.equals(car)
 - equals() is hard with inheritance!

```
Violates LSP
```

```
public boolean equals(Object o) {
  if (o == null) return false;
  if (o.getClass() != getClass())
     return false;
  Car that = (Car) o;
  return ...;
```

```
if (!(o instanceof Car))
     return false;
VS
  if (!(o instanceof SportsCar))
     return false:
```

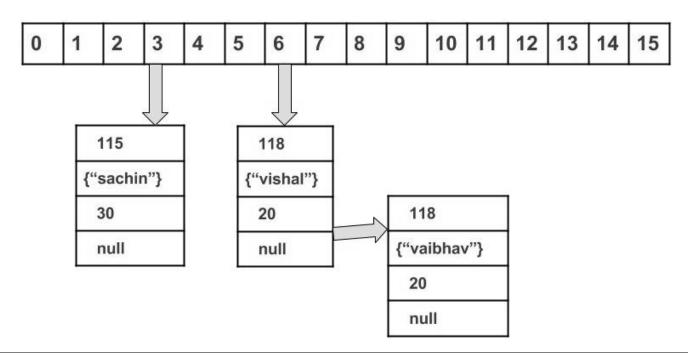

"There is no way to extend an instantiable class and add a value component while preserving the equals contract."

- Joshua Bloch (Effective Java 3rd ed; p42)

hashCode()

hashCode()

- A hash code is... a number that depends on the contents of an object
 - Used in hash-maps/hash-sets.
 - Object's hashCode() hashes the memory address.

Full Example

```
class Car {
  private String make;
  private Date year;
  private int seating;
  private double weight;
 @Override
  public boolean equals(Object o) {
    if (o == this) return true;
    if (!(o instanceof Car)) return false;
   Car that = (Car) o;
    return Objects.equals(make, that.make)
       && Objects.equals(year, that.year)
       && seating == that.seating
       && Double.compare(weight, that.weight) == 0;
  @Override
  public int hashCode() {
    return Objects. hash (make, year, seating, weight);
```

- Use Objects.hash()
 - Pass all fields which store state.

pass in the important fields, they are what we put in .equals()

hashCode() and equals()

If overriding equals(),...

example in AS4 sol only overrides equals()?

you must also override hashCode()

- Hash tables use both methods to find elements:
 Use hashCode() to find the "bin"
 Use equals() to find the object inside the "bin".
- whenever objA.equals(objB) thenobjA.hashCode() must == objB.hashCode()
 - Otherwise collections may not work correctly with the class! can not find them in the hash table
 - Use the same set of fields for computing equals() as for hashCode().

What is wrong with the following?

24-04-02

```
@Override
                                   public class Bucket {
 public int hashCode() {
                                       private String label;
     return 42;
                                       private double cost;
                                       public boolean equals(Object o) {
                                           // ... some code omitted...
                                           return label.equals(o.label);
 Works!
                       Missing
But terrible
                     @Override
efficiency!
                      (optional)
                                       public int hashCode() {
                                           return Objects.hash(cost, label);
     Depending on field not used
            in equals!
                                      need to use same fields in both methods
   x and y might show as equal();
       however have different
        hashCode() values!
```

20

Inheritance with equals() & hashCode()

Defer to base class the work on the base class's fields.

```
// Note: Poor use of inheritance to add a value to
         an instantiable class... but anyway.
class SportsCar extends Car{
    private int topSpeed;
    @Override
    public boolean equals(Object o) {
        if (!super.equals(o)) return false;
                                                                Breaks
        if (!(o instanceof SportsCar)) return false;
                                                               symmetry
        SportsCar sportsCar = (SportsCar) o;
        return topSpeed == sportsCar.topSpeed;
                                             said before, inheritance is nasty with equals()
    @Override
    public int hashCode() {
        return Objects.hash(super.hashCode(), topSpeed);
                 highlight here: can call this super.hashCode()
```

24-04-02 21

clone()

DANGER!

- clone() is for duplicating objects.
- Want to know about clone?
 - Go read Effective Java 3rd ed by Joshua Bloch, Item 13

(Not covered here!)

Use judiciously!

Summary

- Subtilties with Object:
 - toString():
 - For UI only if a simple data object
 - Call super.toString() when needed
 - equals():
 - Check type, cast, check equals
 - Watch for null fields
 - hashCode():
 - Override with equals()
 - Consistent with equals()
